Abstract

This thesis addresses the development of a novel sample thesis. We analyze the requirements of a general template, as it can be used with the \LaTeX text processing system. (And so on...) The abstract should not exceed half a page in size!

Your Central Work

3.1. Definitions and Problem Formulation

In this section describes the relevant physical definitions from which the robustness measure is derived and which will be referred to in the later code implementation.

Examples will be given in terms of laikag quadruped robot as most of the testing of the framework was done with that.

3.1.1. Dynamical Systems

Dynamical systems are distinguished by an evolution of their state $\mathbf{x}(t)$ through time. This evolution can be fully described by a set of ordinary differential equations of the form $\dot{\mathbf{x}}(t) = \mathbf{F}(\mathbf{x}(t), t)$, where \mathbf{F} is some nonlinear function. This simplifies to $\dot{\mathbf{x}}(t) = \mathbf{F}(\mathbf{x}(t))$ under the assumption that the dynamical system is autonomous, i.e. is not explicitly dependent on time. When solving for the explicit solution $\mathbf{x}(t)$, an initial condition $\mathbf{x}_0 = \mathbf{x}(t_0)$ is required, which is a system state at an initial time. For simplicity and without loss of generality for autonomous systems, we set $t_0 = 0$. With this the Initial Value Problem (IVP) can be formulated:

$$\text{find } \mathbf{x}(t) \tag{3.1}$$

$$\text{s.t. } \dot{\mathbf{x}}(t) = \mathbf{F}(\mathbf{x}(t)) \tag{3.2}$$

$$\text{and } \mathbf{x}(0) = \mathbf{x}_0 \tag{3.3}$$

We denote the solution to the IVP as $\mathbf{x}(t, \mathbf{x}_0)$. It represents trajectory of the system state through time given an initial condition. The space in which this trajectory lies is spanned by all possible

3. Your Central Work

states \mathbf{x} and termed the *state space*. Note that any future state of the trajectory $\mathbf{x}(\tau, \mathbf{x}_0)$ at time τ can be interpreted as an initial condition of the IVP itself. It turns out that the new solution coincides with the initial one, i.e. $\mathbf{x}(t, \mathbf{x}_0) = \mathbf{x}(t, \mathbf{x}(\tau, \mathbf{x}_0))$, which illustrates that any state $\mathbf{x}(t)$ of a trajectory $\mathbf{x}(t, \mathbf{x}_0)$ is sufficient to represent the trajectory as a whole.

Mechanical systems (on which we will focus on from here on out) tend to be described in terms of so called generalized coordinates:

$$\mathbf{q}(t) = \begin{pmatrix} q_1(t) & q_2(t) & \dots & q_n(t) \end{pmatrix}^T. \quad (3.4)$$

They are the minimal set of coordinates needed to fully describe the position and orientation of all of the systems elements. Their dimension n coincides with the number of degrees of freedom of the system. The corresponding differential equations are of second order, depending on $\ddot{\mathbf{q}}(t)$ in addition to $\dot{\mathbf{q}}(t)$ and $\mathbf{q}(t)$. Simply put, this is due to their derivation by Newton's second method, where forces acting on the system are related to the second time derivative via $F = ma$. Through an order reduction (Appendix) these differential equations can be cast into the previously mentioned general form 3.1, where

$$\mathbf{x}(t) = \begin{pmatrix} \mathbf{q}(t) & \dot{\mathbf{q}}(t) \end{pmatrix}^T.$$

This implies that in order to solve the IVP, initial conditions \mathbf{q}_0 and $\dot{\mathbf{q}}_0$ are required. We can also state that for a system with n degrees of freedom, $\mathbf{x}(t) \in \mathbb{R}^{2n}$. The particular state space spanned by generalized coordinates and velocities is termed the *phase space*. Within it, any states are single points and state trajectories are smooth curves. The phase space is used for generalizable qualitative analysis of the behaviour of nonlinear dynamical systems and plays a pivotal role in the formulation of the robustness measure.

When discussing high level concepts we will refer to the system state $\mathbf{x}(t)$ for simplicity, while in the code implementation the generalized coordinates $\mathbf{q}(t)$ and its derivatives will be more relevant. Keep in mind that both are equivalent.

3.1.2. Attractors and Convergence

In nonlinear dynamical systems, there may exist sets of states in the phase space which show an attracting behaviour. By "attracting" we mean that once a trajectory reaches an element of such a set, all of its future states will also be part of that set. Define an attractor as a set of states:

$$\mathbf{A} \subset \text{phase space}, \quad (3.5)$$

$$\text{s.t. if } \mathbf{x}(t_0) = \mathbf{x}_0 \in \mathbf{A}, \quad (3.6)$$

$$\mathbf{x}(t, \mathbf{x}_0) \in \mathbf{A} \quad \forall t > t_0. \quad (3.7)$$

Attractors can be divided into two fundamental variants. If the attracting set consists of only one state, it is called a fixed point. Fixed points are associated with the condition

$$\dot{\mathbf{x}}(t) = \mathbf{0} \quad \forall t \in \mathbb{R}, \quad (3.8)$$

meaning that the state of the fixed point is unchanging and the related trajectory is reduced to a point in the phase space. Whether a state $\mathbf{x}(t)$ is a fixed point can be easily determined by

checking $F(\mathbf{x}(t)) = \mathbf{0}$. A classical example of a fixed point is the stable bottom position of a pendulum, where if it starts with zero initial velocity, it won't leave the stable position. This is not the case for any other position as gravity will act on the mass (except for the inverted position, however this is practically not realizable). In the general case with A containing of more than one state, (reference above eq) is not true. Rather the trajectory is moving through the sets of A , visiting every element at some point in time and returning to it in future times in a periodic fashion. These types of attractors are called limit cycles. Finding them is generally a hard problem, but for simpler cases one can check:

$$\text{If for } \mathbf{x}(t, \mathbf{x}_0), t > 0 \quad \exists \quad \mathbf{x}(\tau) = \mathbf{x}(\tau + h), \tau > 0, h > 0, \quad (3.9)$$

$$\{ \mathbf{x}(t) \mid t \in [\tau, \tau + h) \}, \text{ is a limit cycle.} \quad (3.10)$$

An example for this case are the compliant linkages described in (ref strandbeest compliant version), where the end effector follows a cyclic trajectory, i.e. set of states if undisturbed. In the code implementation section, we provide methods for dealing with both types of attractors and the problem of applying the continuous analysis in a discrete setting.

For any initial condition not part of the attractor, the related trajectory may land and stay on the attractor after some time $t > t_0$. We define this occurrence:

$$\text{Given an attractor } \mathbf{A}, \text{ for any } \mathbf{x}_0 \notin \mathbf{A} \quad (3.11)$$

$$\text{if } \lim_{t \rightarrow \infty} \mathbf{x}(t, \mathbf{x}_0) \in \mathbf{A} \Rightarrow \mathbf{x}(t, \mathbf{x}_0) \text{ converges to } \mathbf{A} \quad (3.12)$$

Should the definition above not hold, we denote the trajectory as diverging (as in cell mapping methods).

Note that there may exist any number of attractors in the phase space of a system (reference paper with multitude of attractors). Convergence is always defined with respect to a particular attractor \mathbf{A} , which needs to be specified. Therefore if the trajectory converges to a different attractor, it is still defined as diverging from the attractor of interest.

The set of all states for which the related trajectories converge to the attractor of interest is called the *Basin of Attraction* (BoA) and is defined as:

$$\{ \mathbf{x}_0 \in \mathbb{R}^{2n} \mid \lim_{t \rightarrow \infty} \mathbf{x}(t, \mathbf{x}_0) \in \mathbf{A} \} \quad (3.13)$$

where \mathbf{A} is an attractor as defined in 3.8.

3.1.3. robustness Measure

For the following (no, this) section it is important to have an intuitive understanding of what these abstract definitions mean for actual applications. We will have a single or a set of states of our system that we have as a goal (= attractor). In the context of a quadruped this might be an upright standing position (fixed point) or a periodic walking gait. If the system is perturbed, it's state will inevitably be changed such that it is most likely not part of the attractor anymore. Finding the trajectory shows how the system will further evolve. Now convergence means that under the disturbance applied, in the long term, we will still return to and stay on the attractor,

3. Your Central Work

or the system recovered, it is successful in compensating the disturbance. Divergence means something else happened, which we will just interpret as failure. So if the trajectory related to an initial condition caused by a particular disturbance converges to the attractor, the system is in a sense robust to that disturbance.

If one wants to maximize robustness, really one wants to change the system or rather its parameters in such a manner that the set of disturbances which result in convergence of the state trajectory is maximized. This is the basic formulation.

This basic idea was implemented in REF, with a more focused choice of disturbance space. Disturbances were basically neglected and only their effects in the phase space taken into consideration. So here the goal was to maximize the set of converging initial conditions independent of their cause.

As detailed in REF and REF, evaluating the exact size of the set of converging initial conditions, is often hard and sometimes misleading, which is why the more conservative measure of the minimal radius found with the help of random sampling

When referring to a system being robust to a disturbance, it means that it's trajectory in the phase space will return to the specified attractor under the influence of that particular disturbance.

The size of this set can be interpreted as a measure of robustness, which was done in (REF) and is further described in.

The basic idea of robustness

First explain the concept of the REF robustness measure, not how they actually compute it. Then expand to general disturbance spaces with a pointer to the meaning of $DS = \text{phase space}$

The goal aim of the robustness measure is to quantify the robustness of a system with a particular parameter constellation with respect to a set of disturbances. In REF, these disturbances were chosen to be initial conditions sampled from the phase space. They have a nice physical interpretation. However instantaneous forces are not the only kind of disturbance. Here we will apply the concept of the minimal Radius in REF described to some general disturbance space. This may coincide with or be a subspace of the phase space, but it must not necessarily be the case. At the same time, evolution of the state trajectory and convergence will still be evaluated in the phase space. We choose the method from REF because of it's simplicity in implementation with the given resources (dde).

As in "REFERENCE", the basic idea is that the more disturbances the system can endure, i.e. it converges to the attractor, the more robust it is. Discretizing the DS and simply counting the total number of disturbances the system is robust to is impractical because of the possibly fractal nature of the boundary of the basin of attraction (ref) and the fact that the number of evaluations is $O((1/h)^d)$, meaning that higher resolution and a larger DS will drastically increase computational time. To remedy this issue, the in "REF" proposed minimal Radius is found which denotes the radius of the largest hypersphere that still fits completely within the basin of attraction.

In other words, any combination of disturbances which lies on the surface of the hypersphere with the minimal radius in the DS will result in a trajectory that converges to the attractor in the phase space.

Taking sampling initial conditions from the phase space as disturbances gives a nice physical interpretation and in "REF" this was denoted as general robustness (or was it?), however as a counterexample, periodic or constant disturbances are clearly not covered by this. This is why we worked with general disturbance spaces that can be chosen to work for the particular application at hand. Note that the trajectory will still lie in the phase space and convergence evaluation

Describe robustness measure from paper but for the actual definition use the general disturbance space.

3.1.4. Parameter space and Disturbance space

I feel like this should be part of the robustness measure

separate from "dynamics", focus on

dimension disturbance space equals d

In reference they did it with the phase space

We actively separate phase space and disturbance space for the concept to be more versatile

The disturbance space is defined as the set containing all combinations of disturbances, against which the robustness of the system is evaluated. The choice of disturbances in "REFERENCE" are the initial conditions in the phase space (reference to the section in related work or copy that here) as they can be interpreted as the direct result of external forces. In general however, the disturbances may be chosen arbitrarily and the resulting robustness measure will quantify robustness against these. Examples of this were initial tilting of a quadruped over pitch and roll axes and oscillations with the disturbance space spanning the amplitudes and frequencies. Tuple combinations are favoured because of their ease of visualization and mild computational power requirements.

"REFERENCE" chose the DS to coincide with the phase space, as elements of it can be directly interpreted as the result of external forces on the system. This choice is not always feasible nor necessary, as will be shown in the following sections.

It may coincide with the phase space as implemented in "REFERENCE", in which case disturbances can be interpreted as the effects of external forces acting on the system. This moves the system onto a different trajectory, however it will be shown in the following sections, that this is not always feasible nor necessary. Especially in systems with a large number of degrees of freedom n , the resulting disturbance space is $2n$ dimensional.

case $DS = \text{phase space}$: d

dimension parameter space = p The two main variable spaces of relevance move are the parameter space (PS), where each dimension represents the value of a chosen system parameter. The goal of finding a robustness measure can be thought of as $RM : \mathbb{R}^p \rightarrow \mathbb{R}$, i.e. a mapping from the p -dimensional parameter space to a scalar value. (really it also depends on the disturbance space) Finding the best system parameters with respect to the resulting robustness can be formulated as an optimization problem ...

3. Your Central Work

state space v phase space

3.2. Code Implementation

3.2.1. Framework Overview

differential equations are implicitly represented as simulation objects in dde. Their parameters can be set. The state x as well. Use the solver to compute the trajectory under a disturbance for a given amount of timesteps. check if trajectory converges or diverges. Do this repeatedly with initial conditions sample talk about how knowing the exact shape of the basin of attraction is not necessary for optimization of the robustness, with this and because of the additional work needed to implement the cell mapping algorithms, the method with full trajectories was chosen. For this we need a solver. boom. Great segue!

3.2.2. Solver

Finding an explicit analytical solution to the IVP is possible for simple cases, but very hard if not impossible for more complex systems. The solution to the IVP can be found using numerical solvers. This is not an explicit solution but the trajectory must be iteratively computed by integrating the differential equations over small time steps.

Here we used dde ... write some stuff about dde.

Describe what dde puts out DDE provides q , \dot{q} and \ddot{q} at every timestep when computing the trajectories.

Starting with a sytem of ODE's and as corresponding set of initial states, the first step towards computing robustness measure is finding the resulting trajectories. This is achieved by numerically integrating the differential equations over small timesteps until either convergence is detected or the t_{max} is reached. With the chosen solver it is imperative to keep this timestep constant when comparing different robustness measures. The time step has a direct influence on the solvers accuracy and by that onto the system dynamics. It is advised to find a value that is a sufficient compromise between accuracy and computational time and keeping this fixed from there on.

trajectories here are not continuous but sets of states for discrete timepoints $[t_1, t_2, \dots, t_n]$.

Maybe talk about simulation setup, specifically laikago, that it doesn't do anything but try to keep its limbs in the predefined state.

3.2.3. Detecting Attractors

In order to evaluate wheather a trajectory converges

General idea with similarity of states to attractorstate

Fixed points this is rather easy fixed points are defined states where $\dot{\mathbf{x}}(t) = \mathbf{0} \quad \forall t > t_0$, i.e. $\mathbf{q}(t) = \mathbf{q}_{fp}, \dot{\mathbf{q}}(t) = \ddot{\mathbf{q}}(t) \forall t > t_0$

Periodic Orbits not as trivial. need assumptions assume that period of attractor is the same as forcing frequency. Think controller forcing a gait given period, then the leg will also move at that period. This is not generally true and needs to be verified. Poincare => issues with high computational effort and issues with systems that exhibit oscillations with a multitude of periods.

Issue with wrong attractor

Simplification

sometimes we can loosen the requirements for convergence. For the laikago experiments, where the goal is just for the quadruped to not tip over,

3.2.4. "Evaluating" Convergence

Clearly it is impractical to let t go to infinity, which is why some t_n , max needs to be defined at which the simulation stops. quite similar to

3.2.5. minRad algorithm

maybe not go into too much detail on how it works (look at ref) No DO go into detail. This is the part where we actually want to explain how we find the minimal radius. Because of the random sampling of disturbances, the convergence of the minRad algorithm and therefore the robustness value is inherently stochastic and might be dominated by noise. The extent of this noise can be reduced by larger amounts of samples. A compromise between noise and computational time must be found. Number of iterations

tuning

visualizations plot resolution as a function of iterations. NO, write down the formula $resolution = (1/2)^n$ with n being the number of iterations.

3.2.6. boundarys PS DS

elephant in the room changing even the unit changes the scaling and therefore the robustness value.

explain and give examples on how boundaries were chosen.

was noted in REF that it can be an ellipse as well, but they didn't know how to choose its parameters. We do this by analysis and finding reasonable boundaries in the DS.

order of complexity depending on PS and DS

3. Your Central Work

3.2.7. Multithreading

computational time can be reduced by pseudocode

3.2.8. Application to specific systems

need to decide on PS and DS plus boundaries. Need to find or define attractor.

analysis needed to find parameter space and disturbance space boundaries and good initial guesses. analysis of high dof motion tricky (bad 3d image), rather plot every coordinate over time (image).

applyParameters

simAndEval

3.2.9. Optimization and Complexity reduction

find out how the order of computational effort when making discretization smaller vs how much one bisection algorithm iteration can do. cmaes given robustness value, any optimizer that does not depend on derivatives can be used. Of course one can also just explore the entire parameter space, however that is quite costly. Useful for debugging though (rough estimate if optimizer converges).

complexity reductions should probably be noted where they are implemented (i.e. not in this section)

3.3. Tests

Introduction to laikago high dof rather long computational time. optimization of robustness examples

Laikago Droptest Laikago Swingtest

This is kind of a twist on the concept as we are starting at a fixed point and continually applying disturbances to see for what disturbances the trajectory converges, which in this case is expressed by the system staying at the initial state.

4

Conclusion and Outlook

Implication that the system must be dynamical in nature (i.e. it must evolve). So a rudimentary control strategy must be implemented or outside forced must be applied. Don't quite know where to put this.

further explore effects of combining disturbances of different sorts and the effects of the choice of bounds.

applying to systems of high dof with full phase space

apply to physical dimensions of systems (intuitively more drastic effects)

using the phase space as the disturbance space but heavily restricting it (actuator limits, improbable constellations etc)

4. *Conclusion and Outlook*

Information For The Few (Appendix)

$\text{dot} = f(q, \text{qdot})$ $\text{qddot} = g(q, \text{qdot})$

order reduction:

$x = [q, \text{qdot}] \Rightarrow \text{xdot} = [\text{qdot}, \text{qddot}] = F(x) = [f(x), g(x)]$

$q, \text{qdot}, \text{qddot}$
